10 Abstract

This study examined the interactive relationship between semantic, thematic, and associative 11 word pair strength in the prediction of item relatedness judgments and cued-recall 12 performance. Previously, we found significant three-way interactions between associative, 13 semantic, thematic word overlap when predicting participant judgment strength and recall performance (Maxwell & Buchanan, 2018), expanding upon previous work by Maki (2007a). 15 In this study, we first seek to replicate findings from the original study using a novel stimuli 16 set. Second, this study will further explore the nature of the structure of memory, by 17 investigating the effects of single concept information (i.e., word frequency, concreteness, 18 etc.) on relatedness judgments and recall accuracy. We hypothesize that associative, 19 semantic, and thematic memory networks are interactive in their relationship to judgments and recall, even after controlling for base rates of single concept information, implying a set 21 of interdependent memory systems used for both cognitive processes.

Keywords: judgments, memory, association, semantics, thematics

Modeling Memory: Exploring the Relationship Between Word Overlap and Single Word

Norms when Predicting Relatedness Judgments and Retrieval

Previous research conducted on Judgments of Associative Memory (JAM) has found 26 that these judgments tend to be stable and highly generalizable across varying contexts (Maki, 2007a, 2007b; Valentine & Buchanan, 2013). The JAM task can be viewed as a manipulation of the traditional Judgment of Learning task (JOL). In a JOL task, 29 participants are presented with cue-target word pairs and are asked to make a judgment 30 (typically, on a scale of zero to 100) of how accurately they would be able to respond with the 31 proper target word based on the presentation of a particular cue word (Dunlosky & Nelson, 32 1994; Nelson & Dunlosky, 1991). JAM tasks expand upon this concept by changing the focus of the judgments performed by participants. When presented with the item pair, such as cheese-mouse, participants are asked to judge the number of people out of 100 who would 35 respond with the pair's target word if they were only shown the cue word (Maki, 2007a). 36 This process mimics the creation of associative words norms (i.e., forward strength; D. 37 L. Nelson, McEvoy, & Schreiber, 2004). As such, these judgments can be viewed as the participants' approximations of how associatively related they perceive the paired items to be. The JAM function can then be created by plotting participants' judgments against the 40 word's normed associative strength and calculating a line of best fit. This fit line typically 41 displays a high intercept (bias) and a shallow slope (sensitivity), meaning that participants are biased towards overestimating the associative relatedness between word pairs, and show difficulties differentiating between different amounts of item relatedness (Maki, 2007a). These results are often found in JOL research (Koriat & Bjork, 2005), and they are highly stable across various contexts and instructional manipulations in JAM tasks (Valentine & Buchanan, 2013). 47 Building upon this research, we initially explored recall accuracy within the context of 48

Building upon this research, we initially explored recall accuracy within the context of
word pair judgments, while also expanding the JAM task to incorporate judgments of
semantic and thematic memory. In the pilot study, 63 word-pairs of varying associative,

semantic, and thematic overlap were created and arranged into three blocks, consisting of 21 word-pairs each. Associative overlap was measured with forward strength (FSG; D. L. Nelson et al., 2004), semantic overlap was measured with cosine (COS; Buchanan, Holmes, Teasley, & Hutchison, 2013; McRae, Cree, Seidenberg, & McNorgan, 2005; Vinson & Vigliocco, 2008), and thematic relatedness between pairs was measured with latent semantic analysis (LSA; Landauer & Dumais, 1997; Landauer, Foltz, Laham, Folt, & Laham, 1998). These word pairs were then judged by 112 participants who were recruited from Amazon's Mechanical Turk. Stimuli were arranged into three blocks based, each preceded by a set of instructions explaining either an associative, semantic, or thematic relationship between words. Three versions of the study were created, counterbalancing the order in which judgment instructions and stimuli blocks appeared. Thus, each participant made one set of judgments corresponding to each type of memory, and each word pair recieved each type of judgments.

After completing the judgment phase, participants then completed a cued recall task in which they were presented with the cue word from each of the previously presented word pairs and were asked to complete each pair with the missing target (Maxwell & Buchanan, 2018). Significant three-way interactions were found between database norms when predicting judgments and recall. When semantic overlap was low, thematic and associative strength were competitive, with increases in thematic overlap decreasing the strength of associative overlap as a predictor. However, this trend saw a reversal when semantic overlap was high, with thematic and associative strength complimenting one another. Overall, our findings from this study indicated the degree to which the processing of associative, semantic, and thematic information impacts retrieval and judgment making, while also displaying the interactive relationship that exists between these three types of information.

The proposed study seeks to expand upon this work by extending the original analysis to include multiple single word norms. These norms provide information about different "neighborhoods" of concept information. Broadly speaking, they can be separated into one of three categories. Base values refer to norms which capture information based on a word's

structure. These include part of speech, word frequency, and the number of syllables,
morphemes, and phonemes that comprise a word. Rated values refer to age of acquisition,
concreteness, imageability, valence, and familiarity. Finally, we seek to examine norms that
provide information about the connections a word shares with others based on context.
These norms include orthographic neighborhood, phonographic neighborhood, cue and target
set sizes, and feature set size. These values were selected on the basis of previous research
suggesting their impact on retrieval accuracy; their importance is elaborated upon below.

First, we are interested in assessing the impact of base word norms. Chief amongst 85 these is word frequency. Several sets of norms currently exist for measuring the frequency with which words occur in everyday language, and it is important to determine which of these offers the best representation of everyday language. One of the most commonly used collections of these norms is the Kučera and Francis (1967) frequency norms. This set consists of frequency values for words, which were generated by analyzing books, magazines, and newspapers. However, the validity of using these norms has been questioned on factors 91 such as the properties of the sources analyzed, the size of the corpus analyzed, and the overall age of these norms. First, these norms were created from an analysis of written text. It is important to keep in mind that stylistically, writing tends to be more formal than everyday language and as a result, it may not be the best approximation of it (Brysbaert & New, 2009). Additionally, these norms were generated fifty years ago, meaning that these norms may not accurately reflect the current state of the English language. As such, the Kučera and Francis (1967) norms, while popular, may not be the best choice for researchers interested in gauging the effects of word frequency.

Several viable alternatives to the Kučera and Francis (1967) frequency norms now exist.

One popular method is to use frequency norms obtained from the HAL corpus, which consists
of 131 million words (Burgess & Lund, 1997; Lund & Burgess, 1996). Other collections of
frequency norms include CELEX (Baayen, Piepenbrock, & Gulikers, 1995) based on written
text, the Zeno frequency norms (Zeno, Ivens, Millard, & Duvvuri, 1995) created from

American children's textbooks, and Google Book's collection of word frequencies derived from 131 billion words taken from books published in the United States (see Brysbaert, 106 Keuleers, and New (2011) for an overview and comparison of these norms). For the present 107 study, we plan to use data taken from the both the SUBTLEX project (Brysbaert & New, 108 2009), which is a collection of frequency norms derived from a corpus of approximately 51 100 million words, which were generated from movie and television subtitles and the HAL corpus. 110 SUBTLEX norms are thought to better approximate everyday language, as lines from 111 movies and television tend to be more reflective of everyday speech than writing samples. 112 Additionally, the larger corpus size of both SUBTLEX and HAL contributes to the validity 113 of these norms compared to Kučera and Francis (1967) frequency norms. 114

Next, we are interested in testing the effects of several measures of lexical information 115 related to the physical make-up of words. These measures include the numbers of phonemes. 116 morphemes, and syllables that comprise each word as well as its part of speech. The number 117 of phonemes refers to the number of individual sounds that comprise a word (i.e., the word 118 cat has three phonemes, each of which correspond to the sounds its letters make), while the 119 term morpheme refers to the number of sound units that contain meaning. Drive contains 120 one morpheme, while driver contains two. Morphemes typically consist of root words and their affixes. Additionally, word length (measured as the number of individual characters a 122 word consists of) and the number of syllables a word contains will be investigated, as previous 123 research has suggested that the number of syllables may play a role in processing time. In 124 general, longer words require longer processing time (Kuperman, Stadthagen-Gonzalez, & 125 Brysbaert, 2012), and shorter words tend to be more easily remembered (Cowan, Baddeley, 126 Elliott, & Norris, 2003). Finally, we are interested in the part of speech of each word, as 127 nouns are often easier to remember (Paivio, 1971). Formall defined, part of speech refers to a 128 word's categorization in language based on its syntactic functions. 129

Third, we will examine the effects of norms measuring word properties that are rated by participants. The first of these is age of acquisition, which is a measure of the age at

which a word is learned. This norm is measured by presenting participants with a word and 132 having them enter the age (in years) in which they believe that they would have learned the 133 word (Kuperman et al., 2012). Age of acquisition ratings have been found to be predictive of 134 recall: for example, Dewhurst, Hitch, and Barry (1998) found recall to be higher for late 135 acquired words. Also of interest are measures of a word's valence, which refers to its intrinsic 136 pleasantness or perceived positiveness (Bradley & Lang, 1999). Valence ratings are 137 important across multiple psycholinguistic research settings. These include research on 138 emotion, the impact of emotion of lexical processing and memory, estimating the sentiments 139 of larger passages of text, and estimating the emotional value of new words based on valence 140 ratings of semantically similar words (see Warriner, Kuperman, and Brysbaert (2013) for a 141 review). The next of these rated measures is concreteness, which refers to the degree that a 142 word relates to a perceptible object (Brysbaert, Warriner, & Kuperman, 2014). Similar to concreteness, imageability is described as being a measure of a word's ability to generate a mental image (Stadthagen-Gonzalez & Davis, 2006). Both imageability and concreteness have been linked to recall, as items rated higher in these areas tend to be more easily recalled (D. L. Nelson & Schreiber, 1992). Finally, familiarity norms can be described as an 147 application of word frequency. These norms measure the frequency of exposure to a particular word (Stadthagen-Gonzalez & Davis, 2006). 149

The final group of norms that will be investigated are those which provide information 150 based on connections with neighboring words. Phonographic neighborhood refers to the 151 number of words that can be created by changing one sound in a word (i.e., cat to kite). 152 Similarly, orthographic neighborhood refers to the number of words created by changing a 153 single letter in word (i.e., cat to bat, Adelman & Brown, 2007; Peereman & Content, 1997). Previous findings have suggested that the frequency of a target word relative to that of its orthographic neighbors has an effect on recall, increasing the likelihood of recall for that 156 word (Carreiras, Perea, & Grainger, 1997). Additionally, both of measures have been found 157 to effect processing speed for items (Adelman & Brown, 2007; Buchanan et al., 2013; 158

Coltheart, Davelaar, Jonasson, & Besner, 1977). Next, we are interested in examining two single word norms that are directly related to item associations. These norms measure the 160 number of associates a word shares connections with. Cue set size refers to the number of 161 cue words that a target word is connected to, while target set size is a count of the number 162 of target words a cue word is connected to (Schreiber & Nelson, 1998). Previous research has 163 shown evidence for a cue set size effect in which cue words that are linked to a larger number 164 of associates (target words) are less likely to be recalled than cue words linked to fewer target 165 words (D. L. Nelson, Schreiber, & Xu, 1999). As such, feature list sizes will be calculated for 166 each word overlap norm from the Buchanan et al. (2013) semantic feature norm set. 167

In summary, this study seeks to expand upon previous work by examining how single 168 word norms belonging to these three neighborhoods of item information impact the accuracy 169 of item judgments and recall. These findings will be assessed within the context of 170 associative, semantic, and thematic memory systems. Specifically, we utilize a three-tiered 171 view of the interconnections between these systems as it relates to processing concept 172 information. First, semantic information is processed, which provides a means for 173 categorizing concepts based on feature similarity. Next, processing moves into the associative 174 memory network, where contextual information pertaining to the items is added. Finally, the thematic network incorporates information from both the associative and semantic networks to generate a mental representation of the concept containing both the items meaning and its place in the world. 178

Therefore, the present study has two aims. First, we seek to replicate the interaction results from the previous study using a new set of stimuli. Second, we wish to expand upon these findings by extending the analysis to include neighborhood information for the item pairs. The extended analysis will be analyzed by introducing the different types single word norms through a series of steps based on the type of neighborhood they belong to. First, base word norms will be analyzed. Next, measures of word ratings will be analyzed. Third, single word norms measuring connections between concepts will be analyzed. Finally,

network norms and their interactions will be reanalyzed. The end goal is to determine both which neighborhood of norms have the greatest overall impact on recall and judgment ability, and to further assess the impact of network connections after controlling for the various neighborhoods of single word information.

190 Methods

191 Participants

A power analysis was conducted using the simr package in R (Green & MacLeod, 192 2016), which uses simulations to calculate power for mixed linear models created from the 193 lme4 and nlme packages (Bates, Mächler, Bolker, & Walker, 2015; Pinheiro, Bates, Debroy, 194 Sarkar, & Team, 2017). The results of this analyses suggested a minimum of 35 participants 195 was required to find an effect at 80% power ($\alpha = .05$). However, because power is often 196 underestimated (Bakker, Hartgerink, Wicherts, & Maas, 2016; Brysbaert & Stevens, 2018), 197 we plan to extend the analysis to include approximately 200 participants, a number 198 determined by the amount of available funding. Consistent with the design of the pilot study, 199 participants will be recruited from Amazon's Mechanical Turk, which is a website where 200 individuals can host projects and be connected with a large respondent pool who complete 201 tasks for small amounts of money (Buhrmester, Kwang, & Gosling, 2011). Participants will 202 be paid \$2.00 for their participation. Participant responses will be screened for a basic 203 understanding of study instructions and automated survey responses.

205 Materials

First, mimicking the design of the original pilot study, sixty-three word pairs of varying associative, semantic, and thematic overlap were created to use as stimuli. As with the pilot study, these word pairs were created using the Buchanan et al. (2013) word norm database.

Next, neighborhood information for all cue and target items was collected. Word frequency was collected from the SUBTLEX project (Brysbaert & New, 2009). Part of speech, word

length, and the number of morphemes, phonemes, and syllables of each item was derived from the Buchanan et al. (2013) word norms (originally contained in The English Lexicon 212 Project, Balota et al., 2007). For items with multiple parts of speech (for example, drink can 213 refer to both a beverage and the act of drinking a beverage), part of speech was coded as the 214 most commonly used form. Following the design of Buchanan et al. (2013), this part of 215 speech was determined using Google's define feature. Concreteness, cue set size, and target 216 set size were taken from the South Florida Free Association Norms (D. L. Nelson et al., 217 2004). Feature set size (i.e., the number of features listed as part of the definition of a 218 concept) and cosine set size (i.e., number of semantically related words above a cosine of 219 zero) were calculated from Buchanan et al. (2013). Imageability and familiarity norms were 220 taken from the Toglia and colleagues set of semantic word norms (Toglia, 2009; Toglia & 221 Battig, 1978). Age of acquisition ratings were pulled from the Kuperman et al. (2012) database. Finally, valence ratings for all items were obtained from the Warriner et al. (2013) 223 norms. Stimuli information for cue and target words can be found in Tables 1 and 2.

After gathering neighborhood information, network norms measuring associative, 225 semantic, and thematic overlap were generated for each pair. Forward strength (FSG) was 226 used as a measure of associative overlap. FSG is a value ranging from zero to one which 227 measures of the probability that a cue word will elicit a particular target word in response to 228 it (D. L. Nelson et al., 2004). Cosine (COS) strength was used to measure semantic overlap 220 between concepts (Buchanan et al., 2013; McRae et al., 2005; Vinson & Vigliocco, 2008). As 230 with FSG, this value ranges from zero to one, with higher values indicating more shared 231 features between concepts. Finally, thematic overlap was measured with Latent Semantic Analysis (LSA), which is a measure generated based upon the co-occurrences of words within 233 a document (Landauer & Dumais, 1997; Landauer et al., 1998). Like the measures of associative and semantic overlap, LSA values range from zero to one, with higher values 235 indicating higher co-occurrence between items. The selected stimuli contained a range of 236 values across both the network and neighborhood norms. As with the previous study, stimuli 237

will be arranged into three blocks, with each block consisting of 21 word pairs. The blocks will be structured to have seven words of low COS (0 - .33), medium COS (.34 - .66), and 230 high COS (.67 - 1). COS was chosen due to both limitations with the size of the available 240 data set across all norm sets, and the desire to recreate the selection process used for the 241 previous study. The result of this selection process is that values for the remaining network 242 norms (FSG and LSA) and information neighborhood norms will be contingent upon the 243 COS strengths of the selected stimuli. To counter this, we selected stimuli at random based 244 on the different COS groupings so as to cover a broad range of FSG, LSA, and information neighborhood values. Stimuli information for word pair norms can be found in Table 3. All 246 stimuli and their raw values can be found at https://osf.io/j7qtc/.

248 Procedure

This study will be divided into three sections. First, participants will be presented 249 with word pairs and will be asked to judge how related the items are to one another. This 250 section will comprise three blocks, with each block containing 21 word pairs. Each item block will be preceded by a set of instructions explaining one of the three types of relationships. Participants will also be provided with examples illustrating the type of 253 relationship to be judged. The associative instructions explain associative relationships 254 between concepts, how these relationships can be strong or weak, and the role of free 255 association tasks in determining the magnitude of these relationships. The semantic 256 instructions will provide participants with a brief overview of how words can be related by 257 meaning and will give participants examples of item pairs with low and high levels of 258 semantic overlap. Finally, the thematic instructions will explain how concepts can be 259 connected by overarching themes. These instruction sets are modeled after Buchanan (2010) 260 and Valentine and Buchanan (2013). 261

To clarify, the association instruction set includes the following instructional explanation focusing on the co-occurrence in language: "For example, consider the word

(and concept of) DOG. We often see the word DOG appear in the same context as the word CAT."It's raining cats and dogs." "I have two dogs, but my neighbor has a cat." And so on.

By experiencing the words CAT and DOG together many times, we develop an association

(a mental connection) between them. With lots of this kind of associative learning experience during our lives, we develop a very large and very complex associative memory."

While the semantic instructions focus on the definition and feature overlap of a set of concepts: "Consider the following words (and concepts) TORTOISE, TURTLE, SNAIL, and BANNER. We know that a TORTOISE is a reptile with an exoskeleton and a hard shell. If we compare the word TORTOISE with the word TURTLE, we find that they share a majority of the same features. Therefore, their definitions or characteristics overlap greatly."

Last, the thematic instructions contain a blend of the two instruction sets to focus on both semantic and associative relation: "Words that are thematically related are connected by a related concept and may often occur near each other in language. For example, the word TREE is thematically related to LEAF, FRUIT, BRANCH, and FOREST because they all appear in text together due to related meaning. TREE and COMPUTER would not be thematically related because they would not be in the same writing together."

Participants will then rate the relatedness of the word pairs based on the set of 280 instructions they receive at the start of each judgment block. These judgments will be made 281 using a scale of zero (no relatedness between pairs) to one hundred (a perfect relationships). 282 The instructions for association were: "Assume 100 college students from around the nation 283 gave responses to each CUE (first) word. How many of these 100 students do you think 284 would have given the RESPONSE (second) word?" The semantic instructions were: "Assume both CUE and RESPONSE words have various features like you filled in before. What percent of those features that are the same? Use a scale of 0 to 100, with 0 indicating no relationship, and 100 indicating a perfect relationship." Finally, the thematic instructions 288 were: "Using the two words provided, think about how often those two words would be 289 written together in the same story. Please rate the thematic strength of the following word 290

pairs using a scale of 0 to 100, with 0 indicating no relationship, and 100 indicating a perfect relationship." The complete instructions and examples provided can be found on our OSF page for replication.

Judgments were recorded by the participant typing it into the survey. Participants will 294 complete each of the three judgment blocks in this manner, with judgment instructions 295 changing with each block. Three versions of the study will be created to counterbalance the 296 order in which judgment blocks appear. Stimuli are counterbalanced across blocks, such that 297 each word pair is seen once per subject but evenly spread across all three judgment types. 298 Word pairs are randomized within each block. Participants will be randomly assigned to 299 survey conditions. After completing the judgment blocks, participants will be presented with 300 a short distractor task to account for recency effects. This section will be timed to last two 301 minutes and will task participants with alphabetizing a scrambled list of the fifty U.S. states. 302 Once two minutes elapses, participants will automatically progress to a cued recall task, in 303 which they will be presented with each of the 63 cues that had previously been judged as 304 cue-target pairs. Participants will be asked to complete each word pair with the appropriate 305 target word, based on the available cue word. Presentation of these pairs will be randomized, 306 and participants will be informed that there is no penalty for guessing. The Qualtrics 307 surveys are uploaded at https://osf.io/j7qtc/. 308

Results

First, the results from the recall section will be coded as zero for incorrect responses and one for correct responses. NA will be used to denote missing responses from participants who did not complete the recall section. Responses that are words instead of numbers in the judgment phase will be deleted and treated as missing data. Data will then be screened for out of range judgment responses (i.e., responses greater than 100). Recall and judgment scores will be screened for outliers using Mahalanobis distance at p < .001 (Tabachnick & Fidell, 2012), and multicollinearity between predictor variables will be measured with

Pearson correlations. Data will then be screened for assumptions of normality, linearity, homogeneity, and homoscedasticity. Descriptive statistics of mean judgment and recall scores will be reported for each judgment condition.

Multilevel modeling will then be used to analyze the data (Gelman, 2006) to control 320 for the nested structure of the data using the nlme library. Each participant's judgment and 321 recall ratings will be treated as a data point, using participants as a nested random intercept 322 factor. As part of our replication, we will reanalyze these new stimuli using COS, FSG, LSA, 323 and their interaction to predict judgments and recall separately as the dependent variables. 324 Just as in Maxwell and Buchanan (2018), judgment condition was used as a control variable. 325 Variables will be mean centered prior to analysis to control for multicollinearity. If a 326 significant three-way interaction occurs, simple slopes analyses will be used to explore that 327 interaction. We will examine low (-1SD), average (mean), and high (+1SD) COS values for 328 two-way interactions of FSG and LSA. If these values are significant, LSA will be further 329 broken into low, average, and high simple slopes to examine FSG. α is set to .05 for analyses. 330 We predict that the interaction found previously will replicate on a new set of stimuli. 331

A second set of analyses will be performed using the Maxwell and Buchanan (2018) 332 stimuli set and this new stimuli set combined, examining the hypothesis of interactive 333 networks after controlling for base word norm information. Stimuli sets from both studies 334 will be combined to create a larger range of stimuli and values across normed information. 335 These neighborhood norms will be added introduced into each model in steps, after 336 controlling for judgment condition. Initially, base word norms will be added, followed by 337 lexical information, rated properties, and norms measuring neighborhood connections, as described in the introduction and methods. Each set of variables will be used to predict the 339 dependent variables of judgment and recall, again as a multilevel model. Each variable will be discussed in the step of the analysis it was entered. We expect that many of these variables will significantly predict judgments and recall, but do not predict which ones in 342 particular. Last, the interaction of network norms will be added to the model with the

prediction that the interaction of COS, FSG, and LSA may be significant, even after controlling for single concept information.

This analysis plan was pre-registered as part of the Pre-Registration Challenge through the Open Science Foundation and may be found at: https://osf.io/24sp9/. This manuscript was written in R markdown using the papaja package by Aust and Barth (2017). References
